Abstract

During the underground coal gasification (UCG) process, fracturing and cracks occur inside the gasification zone and surrounding rocks as the underground coal cavity evolves. Although fracturing activity and crack extension directly affect gasification efficiency and have environmental impacts, little research to date has focused on their effects. This study discusses the application of acoustic emission (AE) analysis for the evaluation of distinctly designed UCG models and operational parameters and describes the gasification process based on its results. We studied the cavity growth, fracturing mechanism, and the effects of various design and operational variables, such as linking-hole type, gas feed rate, and gasification agent. We found that the AE activity was closely related to the temperature change occurring inside the coal, with AE generation apparently resulting from crack initiation and extension around the coal gasification area, which occurs as a result of thermal stress. UCG modeling showed that the location of AE sources reflects the size of the gasification area and the cavity growth. In addition, the quantitative information on the located AE sources can be obtained. The introduction of a process control system into UCG modeling along with AE monitoring allowed for the real-time monitoring of the fracturing and cavity evolution inside a combustion reactor. Together, these processes have the potential to significantly reduce field risk in UCG by enabling the timely adjustment of operational parameters. Thus, AE monitoring is useful for maintaining a safe and efficient UCG process.

Keywords: Acoustic emission (AE); Underground coal gasification (UCG); UCG model; Cavity growth; Crack distribution

1. Introduction

Fossil fuels remain the primary energy source worldwide, and coal, the most abundant fossil fuel source, is responsible for providing a high percentage of electricity generation. Most power plants still use combustion processes [1, 2] and are responsible for the emission of stationary-source carbon into the air. As the largest developing countries with maximal coal yield and consumption, China and India use coal as their primary energy source. In particular, considering the amount of coal in India and its high ash content (13.5%–50%), low calorific value, and seam depth, there is a distinct need to make better use of these resources [3, 4]. Increasingly serious climate and environmental problems have also spurred interest in research on the development of clean and efficient coal technologies. Underground coal gasification (UCG) is a promising environmentally acceptable technique for the utilizing coal reserves, particularly those at great depths or under complicated geological conditions that are unmineable or uneconomic with conventional production methods [5–12]. UCG involves the gasification of coal within the seam via a process of injecting oxidants through an injection well and extracting the resulting syngas through a production well. This process has only a modest environmental impact and produces an easily transportable product that can serve as fuel gas or chemical feedstock or be used for liquid fuel production [13, 14]. In some cases of deep coal seam, many UCG operations also create by-product of CO₂ suitable for developing an UCG-CCS (carbon capture and sequestration) system with the technological development of CO₂ capture and storage [5, 10, 15–18]. Hydrogen production from underground coal gasification has also been pursued in recent years [19–22]. UCG has several advantages over surface coal gasification, including cost efficiency, elimination of ash waste, and provides the potential site (cavity formed in underground) for carbon sequestration [8, 23].

The idea of UCG was first proposed by Sir William Siemens in 1868 [24] as a means of solving the problems of smoke pollution in industrial cities. Instead of burning coal at the surface, he suggested placing a conventional surface coal gasifier into a mine and gasifying waste and slack coal underground. Two decades later, Dimitri I. Mendeleev noted that gasifying coal *in situ* could potentially lower cost inputs (less equipment for excavation), improve labor safety (with no underground labor required), and allow for more convenient transportation (gas pipeline transport) than traditional mining [25, 26]. In 1910, an American engineer Anson G. Betts who were granted three patents for inventing a method of gasifying the unmined coal and considered effect of various important factors on coal gasification *in situ* [27–29]. Jolley *et al.* reported early experimental attempts to the underground coal gasification [30–32].

Owing to these significant advantages, UCG has been attempted in many countries through laboratory-scale experiments and field tests [33–43], and was even applied in the USSR for industrial scale power production [5]. Recently, there has been an increased interest in UCG study [44–48] and many noteworthy modeling investigations were developed for investigating the various effects on gasification efficiency, flame propagation, coal consumption, etc. However, the process incurs

1 potential risks in the form of surface gas leakage, groundwater contamination, and surface depression
2 as a result of improper UCG operation or other unpredictable factors, as coal spalling and the evolution
3 of the underground cavity causes changes to the target coal seam and surrounding rock layers. In the
4 1970s and 1980s, dozens of UCG trials were performed in the U.S.; three of these tests (Hoe Creek I,
5 II, and III) at Hoe Creek, Wyoming [49–52] produced water contamination and subsidence that were
6 possibly caused by over-pressurization and excess fracturing in the gasification area. Environmental
7 risk assessments require the consideration of cracking under high cavity temperatures, cavity growth,
8 and the fracture mechanism during and after the UCG process. There is little information available in
9 literature about the fracturing activities with the crack initiation and extension around underground
10 gasifier during UCG process. Therefore, a precise evaluation of the combustion area of the
11 underground coal seam is necessary. In particular, monitoring of fracture activity in the coal seam and
12 surrounding rock is important not only for efficient gas production but also for the estimation of
13 subsidence, pollution of underground aquifers, and gas leakage to the surface. The creation of a
14 combustion reactor in an underground coal seam during the UCG process involves the flow of oxygen
15 and other gases through an injection well and the collection of heat energy and gases from a production
16 well. As gasification progresses, the combustion reactor is moved along the linking hole. In this
17 process, the fracturing activity inside the coal seam serves an important role in enlarging the
18 gasification zone through a process of continuous surface area oxidization caused by coal cracking. For
19 effective coal gasification, this fracturing activity must be controlled. Moreover, excess fractures inside
20 the coal seam and surrounding rock can induce cavity collapse, subsidence, contamination of local
21 freshwater aquifers, etc. Therefore, monitoring and controlling of fracturing activity in underground
22 areas are key technological requirements for efficient and safe UCG. The main objective of this study
23 was the assessment of the feasibility of applying a new approach i.e., acoustic emission (AE)
24 technologies for monitoring cavity growth during the UCG process in order to determine the
25 mechanism of AE generation and then visualize fracturing activities in the gasification zone. To this
26 end, a series of ex-situ UCG models were constructed. During coal combustion, temperatures inside
27 the coal, contents of the product gases (reported in literature [53]), and AE activity were successively
28 monitored at controlled feed gas (air/oxygen and steam) flow rates. Based on this, crack distribution
29 models were developed using AE moment tensor analysis. The obtained results can be used for the
30 observation of fracture configuration and cracks in order to develop fundamental data to be used in
31 technology and simulation methods for evaluating the combustion zone during UCG.

32 **2. Material and methods**

33 *2.1. Description of the experimental setup*

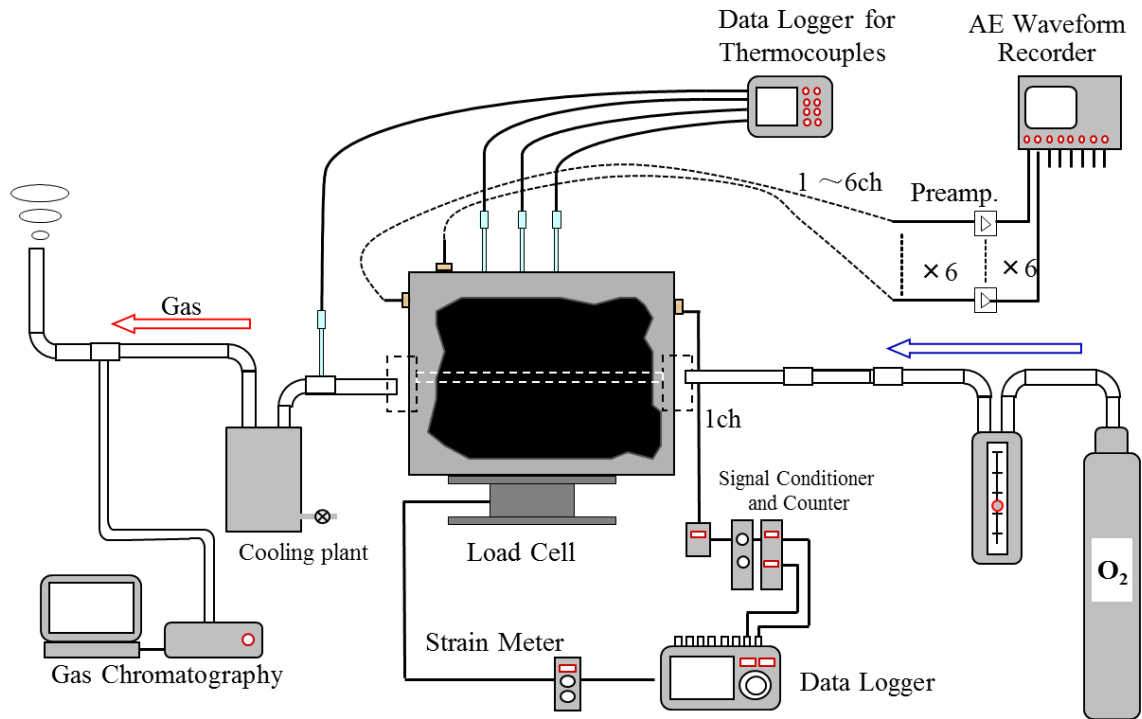

34 In this study, experimental simulation of UCG in coal block samples was conducted using ex-situ
35 laboratory UCG models, which were used to analyze fractures occurring in the gasification zone by
36 varying several operational parameters (linking-hole type, feed gas, operational time, etc.).

37 The coal samples for the UCG trials were obtained from the Kushiro and Bibai Coal Mine located
38 in Hokkaido, Japan. This coal is bituminous and characterized by a high sulfur and relatively low
39 moisture content [53]. The raw coal blocks were shaped into rectangular cross sections and cast in a
40 drum can with concrete in order to simulate both the coal seam and the surrounding rock layers. The

1 reactor walls were made of heat-resistant concrete of a specific thickness, thus providing an internal
2 active space.

3 A schematic of the gasifier structure is shown in Fig. 1. This setup consists of the simulated gasifier,
4 a gas agent supply system, a syngas cooling plant, and a gas chromatograph for analyzing the product
5 gas compositions at specific sampling times. The location and propagation of the gasification zone
6 were monitored by measuring the temperature using thermocouples and by monitoring fracture using
7 AE sensors equipped within the models.

8

9

10 **Fig. 1.** Schematic of ex-situ experimental setup.

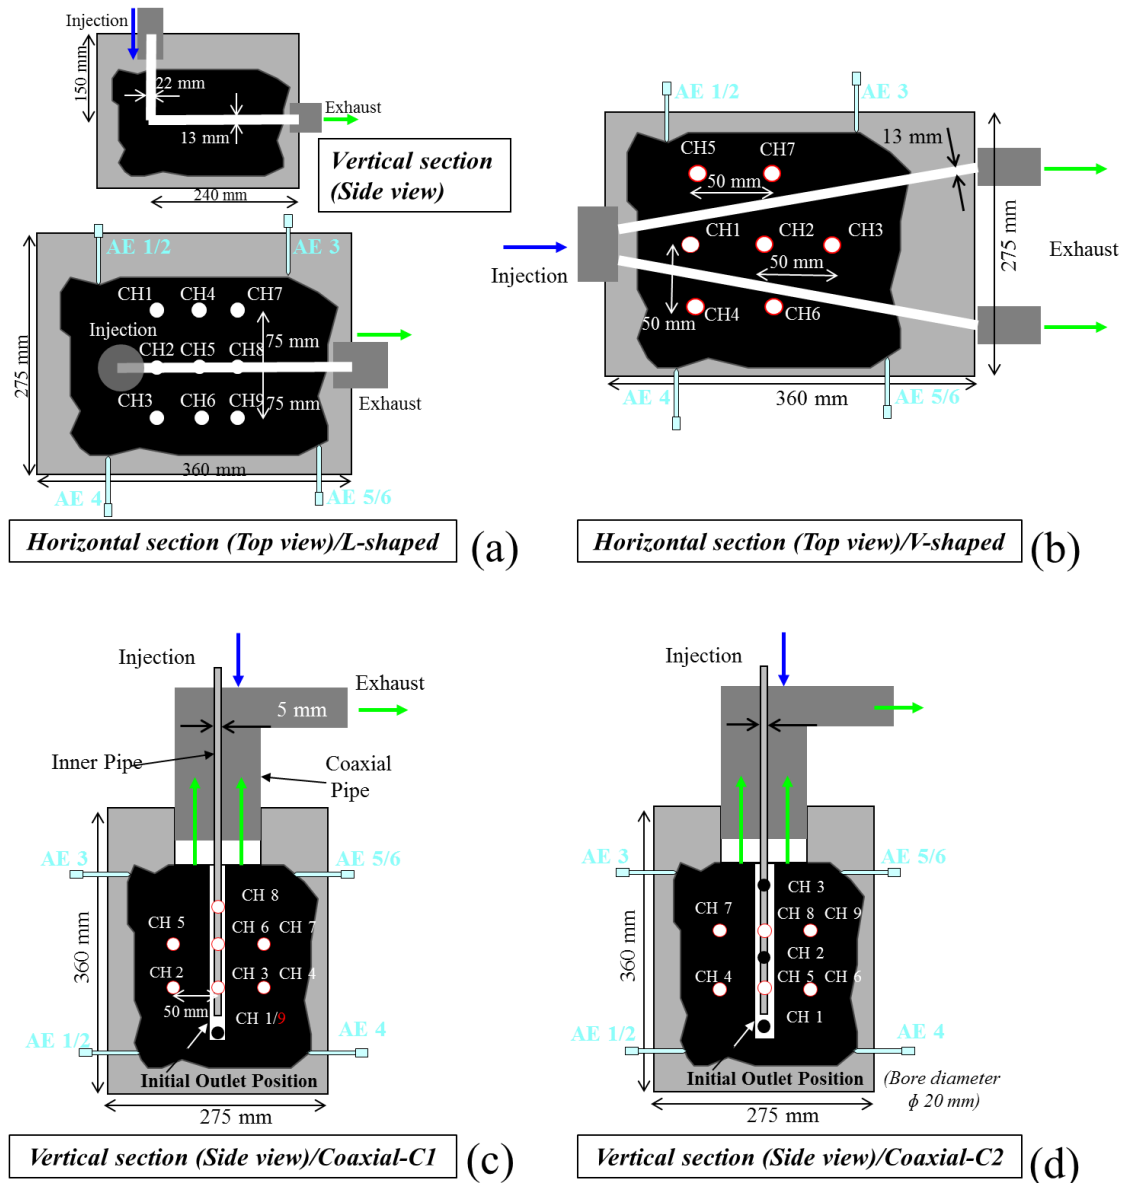

11

12 In a typical UCG process, two vertical wells are drilled into the coal seam and designed for the
13 injection and production, connected by an underground gasification gallery created using various
14 linking techniques at some distance apart. However, it is difficult to employ a universal design of UCG
15 system directly to a target underground coal seam which is buried in a complex geological structure or
16 need to consider the ground conditions. An underground reactor is created in an UCG system, which
17 expands around the gasification channel. The underground-link, i.e., gasification channel between two
18 wells needs to be established in the target coal seam as the underground primitive conditions,
19 surrounding rock characteristics, and coal properties cannot readily provide a porous gasification
20 channel for the gas flow and continuation of gasification process. Moreover, the geometry and
21 dimensions of the experimental model seem to affect the product gas parameters and gasification
22 efficiency. In this study, three link methods, namely, V-shaped and L-shaped linking-holes and
23 Coaxial-hole UCG models were designed and conducted.

24 The sections and dimensions of the typical simulated L-shaped (L), V-shaped (V) linking-hole
25 models, and Coaxial-hole models (C1 and C2) used in this study are shown in Fig. 2. In each model, an
26 irregular rectangular coal block was cast in the drum can ($\varnothing 27.5 \times 36$ cm) with heat-resistant concrete.
27 As shown in the figure, the linking holes set in the models for supplying the reactant gas, extracting

1 production gases, and also worked as the gasification channel. Wherein, the 22-mm-diameter injection
 2 hole of the L-shaped model was drilled for convenient ignition and injecting the reactant gas. As
 3 shown in Fig. 2 (b), the V-shaped 13 × 13 mm linking-hole was prepared for injection and production.
 4 In the coaxial-hole UCG model (C1 and C2), a thin inner pipe used for the injection of oxidant is
 5 located within an outer pipe that serves as a gas production outlet. To adjust the outlet position,
 6 the inner pipe is slid up and down. And the distinct type of reactant gas (pure oxygen/C1, and gas mixture
 7 of air and oxygen/C2) is employed in these two experiments. The figure also shows the locations of the
 8 thermocouples and the AE sensor arrangement. The positions of the thermocouples mounted inside the
 9 models are denoted as “channel (CH)” as shown in the figure.

1 2.2. Process control and AE monitoring

2 In this study, pure oxygen derived from a feeding gas system consisting of a high-pressure oxygen
3 cylinder, a steam-generating plant, and a flow rate controller was used as the gasification agent. To
4 initiate combustion, a gas burner was passed through the injection hole. The ignition process lasted a
5 short period of time (5–10 min). After confirmation that the coal block had ignited in the designed
6 position, pure oxygen was continuously supplied to the gasifier for the remaining time of the
7 experiment, which was terminated when the fire front reached the coal block border by stopping the
8 oxygen supply, leading to a quick combustion halt and a suppression of gasification.

9 To measure the gasification cavity evolution and the temperature changes inside the reactor, the
10 thermocouples were placed at depths just touching the coal block surface, i.e., at the border between
11 the coal block and the heat-resistant concrete, or directly next to the gasification channel. The AE
12 events and count rate from sensors mounted inside a coal block or pasted on the model surface were
13 recorded using a data logger (GL900; Graphtec Corp., Yokohama, Japan), which respectively depict
14 the frequency of AE occurrence, i.e., the amount of cracks initiated inside coal and the magnitude of an
15 AE event. For each model, AE waveforms from sensors were recorded using a multi-recorder (GR-
16 7000; Keyence Co., Osaka, Japan) with a sampling time of 5–10 μ s. Changes in the gas composition,
17 AE count rate and events, and the distribution of temperatures in a UCG model were measured over
18 the course of each experiment.

19 3. Results and Discussion

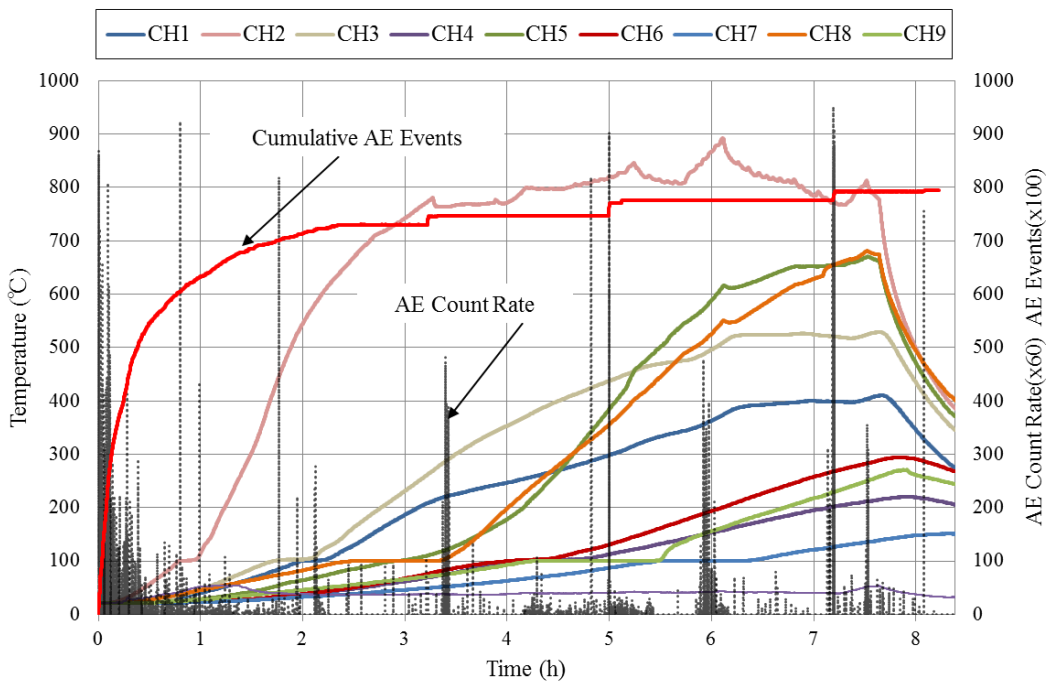

20 Principal results in terms of product gas concentrations, gasification rates, etc. from the V, L, and
21 C1 model experiments were discussed in our earlier work [53]. Energy recovery was also evaluated by
22 using the proposed stoichiometric method. To optimize the UCG process and avoid potential risks, it is
23 important to monitor the gasification process and understand the fracturing activities occurring in the
24 coal seam, especially in the zone around the gasification cavity that is exposed by the propagation of
25 combustion fracturing. In this study, we investigated the fracturing behavior, the cavity growth with
26 crack extension, and the crack distribution using measured AE data obtained from the previous V, L,
27 and C1 studies as well as a new C2 UCG model study. Calorific values obtained by the respective
28 models are shown in Fig. 3, from which it is seen that significantly higher calorific values were
29 obtained using linking-hole UCG systems under the given experimental conditions. Further coaxial
30 model experiments were performed under similar conditions for different operational times (14 h for
31 C1 and 19 h for C2) and hole diameters (13 mm for C1 and 30 mm for C2). Data on product gas
32 concentration in the C1 model are not accessible for the period between 5.7 and 7.3 h. For the C2
33 model experiment, we successfully collected only gas components during the 6.5 h gasification
34 process. As expected, the calorific value of the product gas was higher, and effective combustion
35 lasted longer when a bigger coaxial hole was used.

3 coaxial-hole models.

4
5 *3.1. Effect of the local temperature on AE count rate and event*

6 Following ignition of the coal, pure oxygen was supplied to enable gasification over the duration of
7 the experiment. In the L-shaped UCG model, two linking holes were formed for gas production: one
8 for injecting gasification agents from the upward side, and the other for exhausting gas production, as
9 shown in Fig. 2. Temperature variation and AE activities that occurred inside the coal block during the
10 experiment are shown in Fig. 4 for the case of the L-shaped UCG model wherein the gasification
11 process was sustained at an oxygen supply rate of 3.8–5 L/min.

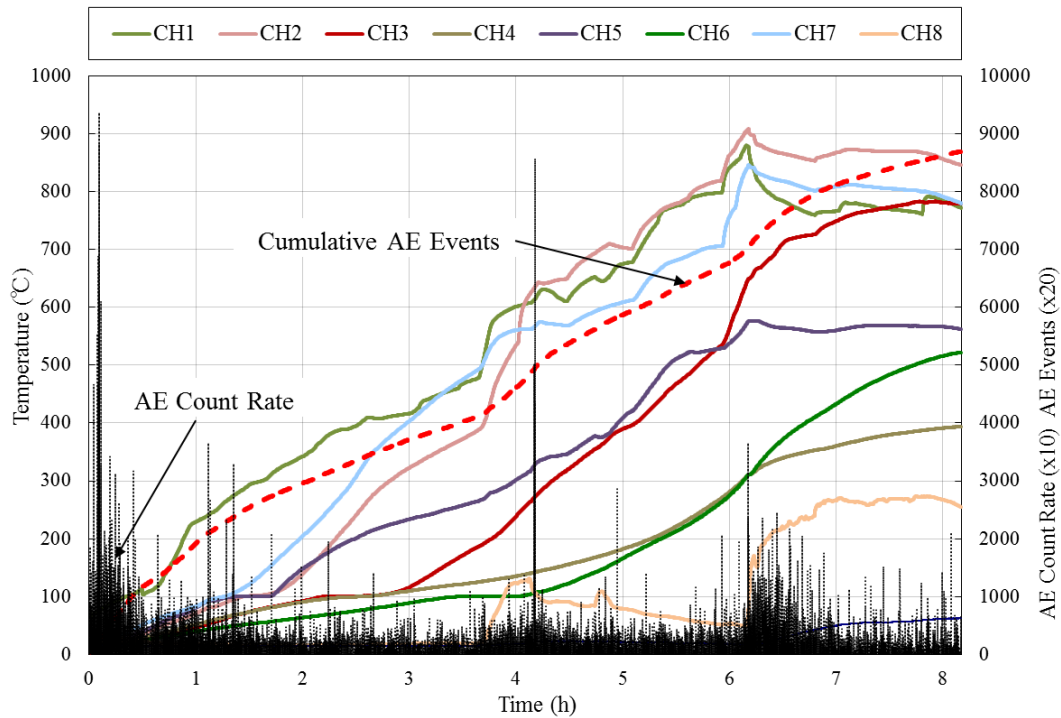

13
14 **Fig. 4.** Variation of AE activities (count rate/event) with temperature change vs. time in L model
15 experiment.

During the experiment, fracturing occurred inside the gasification area under the coal burning. The AE count rate reflects the magnitude of the resulting AE activity, with the number of AE events corresponding to the number of cracks initiated inside the coal samples. During the initial period, the temperature at position CH2 grew rapidly to a high level, which demonstrates that the combustion area was formed near the ignition position. The results demonstrate that the number of AE events and the AE count rate increased rapidly with changing CH2 temperature at the beginning of the experiment. Comparison of several peak values at CH2 with AE events/count rate reveals a mutual correlation, i.e., at the time of local peak temperatures, AE activity was high. During the same time period (0–2 h, Fig. 3), the calorific value of the combustible gas also rose in the L model. Subsequent temperature readings from thermocouples CH1 and CH3 reveal a relatively high growth rate after approximately 2.2 h at each side of the gas inlet. At approximately 3.5 h, the high temperature zone started to move toward the outlet side, as reflected by the rapid increase of the temperature at CH5 and CH8 (Fig. 2). It is also seen that AE activity also occurred and the count rate hit several peaks during these time periods. We stopped the oxygen flow after 7.2 h of operation, resulting in a sudden drop in the temperature of the combustion area with the increment of AE events.

In the V-shaped model experiment, oxygen feed gas was blown into the reactor at a flow rate of approximately 5 L/min in order to heat the coal block and accumulate a sufficient amount of thermal energy for gasification process development. Fig. 5 shows the temperature changes and AE activity occurring within the V model during this test. The results show a cumulative rise in AE events with increasing temperature. The temperature recorded at CH1 maintained relatively higher growth before 3 h of operation, which demonstrated that the combustion area was formed early in the experiment near the ignition area (near CH1) in the early stage. But it can be seen that, after about 2.5 h, the temperature recorded at each thermocouple rose slowly except of the CH1, CH2 and CH7. The higher zone moved along the upper linking-hole (CH2, CH7) in the middle period. This is because an inherent large crack exists in the coal block sample applied in this experiment, which locates in the area between CH2 and CH7 and roughly along the upper linking-hole. Saulov D.N. et al [44] reported the valuable work for investigating the influencing factors of flame behavior (position and propagation) in gasifier, such as primary physical parameters, injection rate, mass balance, etc. by establishing a theoretical model. At about 3.9 h, the flow rate of feeding gas was changed temporarily from 4.5 to 7 L/min. But the gasification zone propagated along the upper linking-hole as before and high temperature zone located around the CH2 and CH7, because the inherent large crack is still the dominant factor at this period. The thermocouple at CH8 was used to measure the temperature of the product gas at the outlet. The CH8 measurements indicate that local temperatures rose gradually, reaching as high as approximately 900 °C; it can be inferred that this highest temperature value is the temperature of the cavity roof, where combustion occurs. The feeding gas flow rate was continuously increased to 8 L/min at about 5h. The temperature around the location of CH3 and CH6 increased abruptly and the gasification zone gradually propagated along the lower liking-hole can be inferred. The AE count rate and number of cracking events increased markedly during the periods of rapid temperature growth between 3.5–4.5 h and 6–7 h; in particular, both measures attained high values at around 4.1, 4.8, and 6.2 h. The recorded temperature of the product gas also changed considerably and peaked around these times. These observations demonstrate that AEs are more significant when the

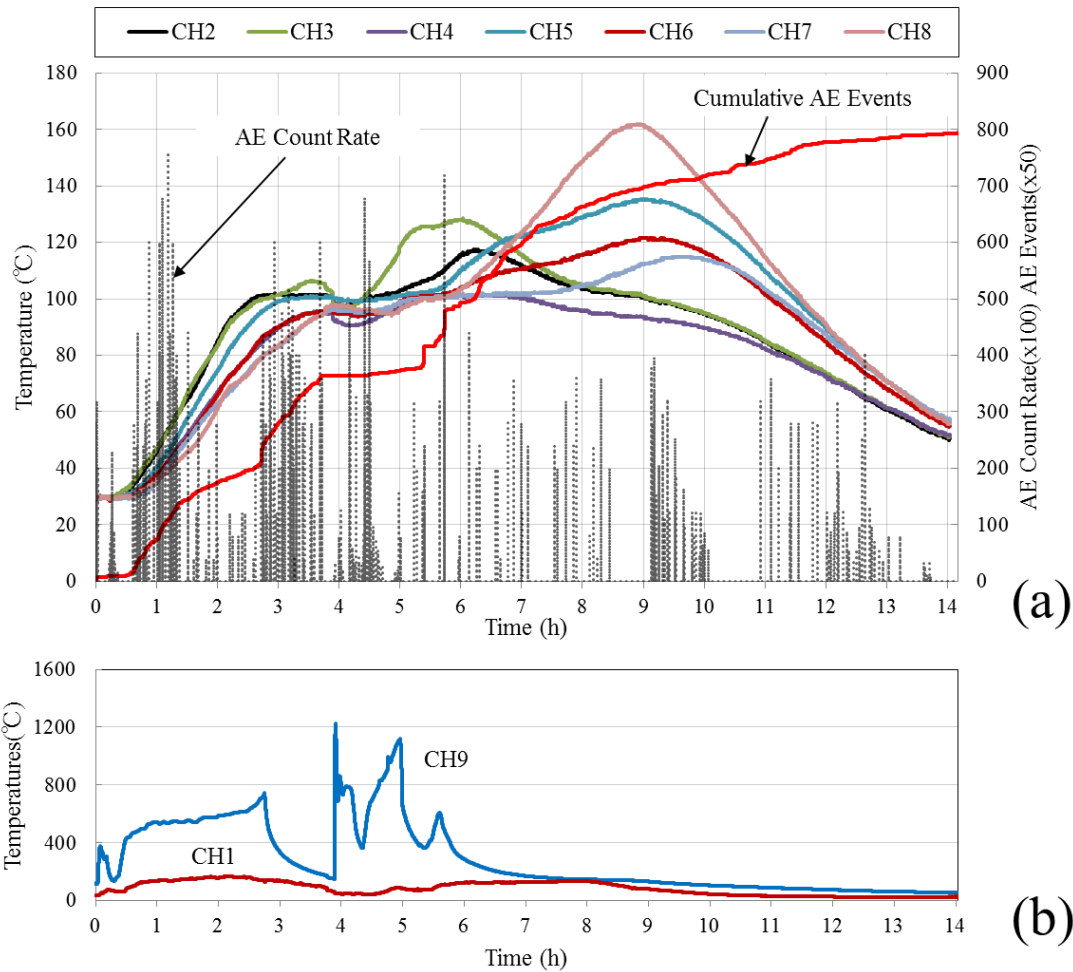

1 temperature fluctuates significantly inside the reactor. After rising the flow rate of feeding gas at 4 h;
 2 from Fig. 5, it is seen that the temperature increased sharply near this point. Both AE activity and the
 3 calorific value of the synthesis gas rose after the oxygen supply rate increase at 4 h (Fig. 3); the results
 4 also indicate expansion of the gasification process and combustion area. After more than 8 h of
 5 operation, the global temperatures inside the reactor appeared to continuously decline, indicating that
 6 the gasification zone arrived at the outlet of the model, likely initiating the termination of the
 7 gasification process.
 8

9
 10 **Fig. 5.** Variation of AE activities (count rate/event) with temperature change vs. time in V model
 11 experiment.

12
 13 For comparison, coaxial-hole model experiments were conducted in the laboratory using similar
 14 operating parameters to those used in the oxygen-fired V- and L-shaped model experiments just
 15 described. In a general UCG system, two boreholes, for air/oxygen injection and gas production, are
 16 drilled from the surface to the target coal seam using a linking hole as gasification channel. However,
 17 under complex coal seam conditions, traditional linking methods may be unusable or uneconomic. The
 18 coaxial-hole UCG method is expected to be useful for producing local energy in small communities
 19 because of its wide tolerance to environmental geological conditions and because the costs of
 20 constructing a single coaxial drill hole and ground plant facility are lower than those of conventional
 21 UCG using a linking hole.

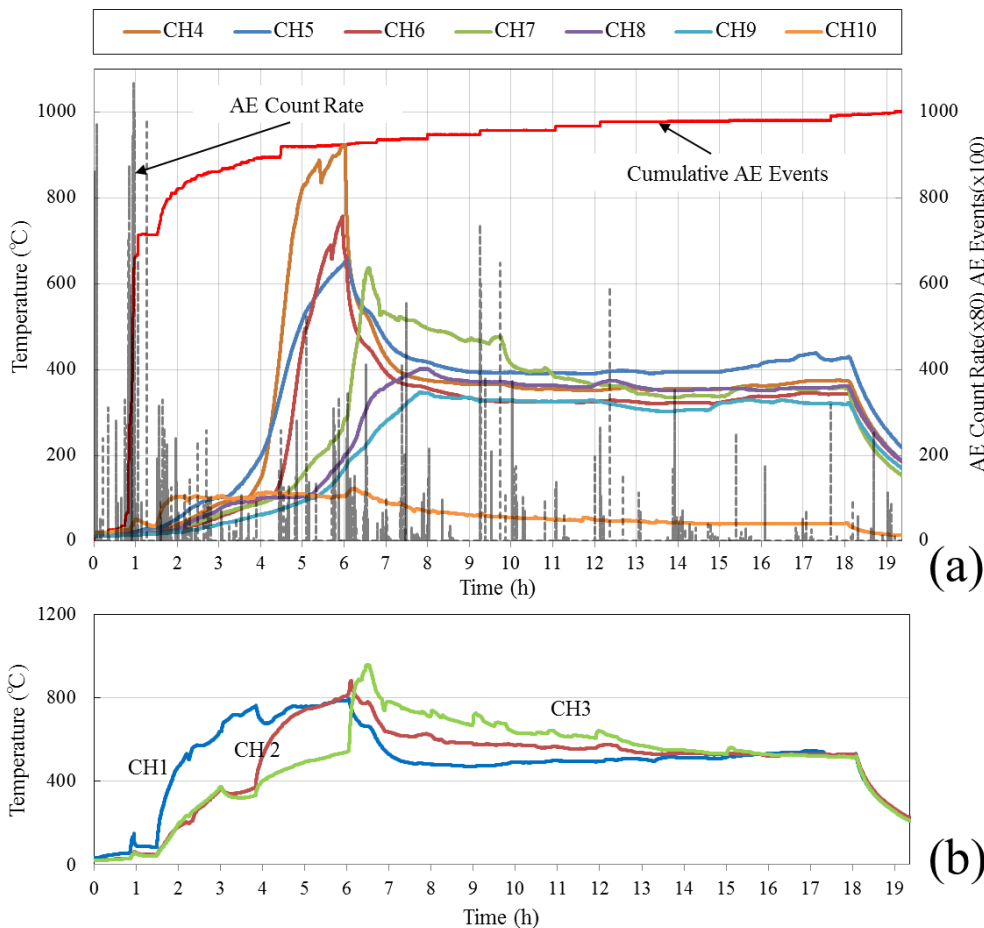

22 **Fig. 6(a)** shows the temperature increase at CH2–CH8 measured throughout the combustion process
 23 and the AE activity as a function of operation time for a C1 coaxial-hole model experiment. The
 24 temperature profiles of CH1 and CH9, which detected the temperatures of the gasification channel and
 25 the gas stream, are shown in **Fig. 6(b)**.
 26

1
2 **Fig. 6.** Variation of AE activities (count rate/event) with (a) temperature change vs. time and (b)
3 temperature profiles in gasification channel/product gas outlet vs. time in C1 model experiment.

4
5 Gasification carried on for approximately 14 h at the operating parameters used in the experiments
6 described above, with a changing flow rate averaging 4.0 L/min. The results show that the number of
7 AE events and the AE count rate increased rapidly in the early stage of the experiment as the
8 temperature rose inside the model. It is apparent that the AE events and AE count rate were active
9 during the initial part of the experiment. The temperature at CH3 steadily increased to approximately
10 100 °C, indicating the temperature of the corresponding coal block surface; from this, the formation of
11 a combustion area near the ignition area (i.e., near CH3) can be inferred. After approximately 3.25 h,
12 the experiment was stopped for approximately 30 min, which caused the temperature of the reactor to
13 drop and resulted in a considerable increase in AE events. After about 5 h and 7 h, the temperatures
14 recorded by thermocouples CH2 and CH3 and by thermocouples CH5 and CH6 gradually increased
15 and reached respectively high levels. It can be seen that the gasification zone gradually propagated
16 from bottom to the upper part. Two peak calorific value values (Fig. 3) were obtained during these two
17 time periods. After this, the temperature at CH8 continued to rapidly grow to its highest value,
18 corresponding to a relatively high AE count rate, which depicts the reaction zone has arrived at the top
19 of the model. During the course of this later period, a gradual drop in temperatures in the gasification
20 zone was observed, indicating that the reaction area had moved to the coal block border.

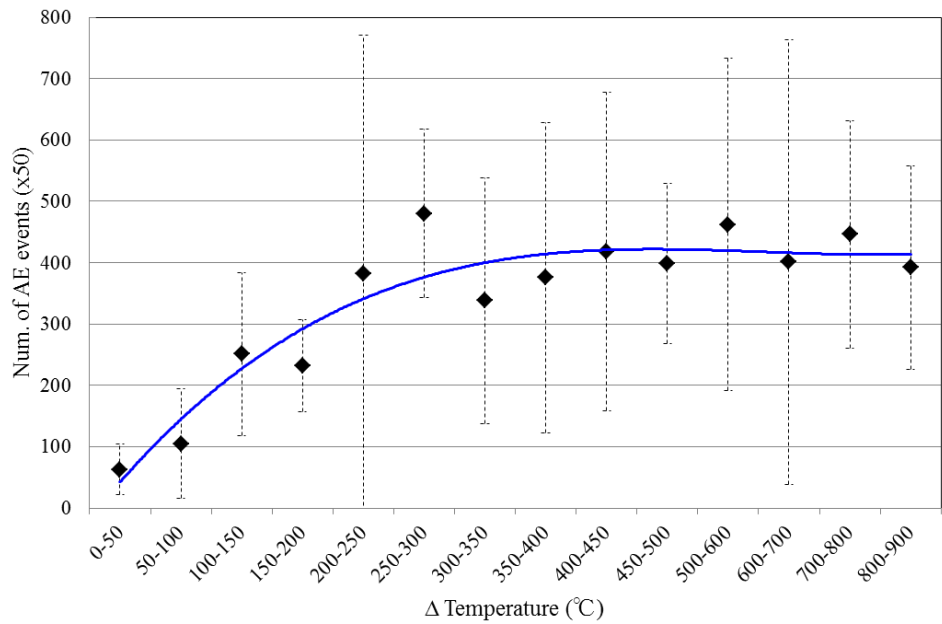

1 The C2 model experiment was conducted using a mixture of air and oxygen (with an oxygen
 2 concentration of approximately 35%) as a gasification agent. At 0–6 h, the air/oxygen was injected into
 3 the gasifier at an average flow rate of approximately 10.0 L/min. During the remainder of the process,
 4 only air was provided for gasification. Variations of temperature and AE occurring in the C2 model are
 5 shown in Fig. 7(a). The temperature profiles of CH1, CH2, and CH3 (Fig. 7(b)) show the growth of the
 6 gasification channel (as shown in Fig. 2) from the bottom to the top part of the coaxial hole. After
 7 beginning, thermocouples of CH5 recorded a relatively high temperature, it can be inferred that the
 8 combustion area was formed around the bottom of model (ignition position). Three hours after the start
 9 of high AE activity in the initial phase, the temperatures of the thermocouples rose considerably. After
 10 about 4 h, and again after 6 h, the temperatures of CH 4–6 and CH 7–8 respectively increased rapidly
 11 and reached the highest value. It shows that the combustion zone moved from the lower part to the top
 12 part of the coal block. This result also can be clearly seen in Fig. 7(b), the temperature recorded by
 13 CH1, CH2 and CH3, had a significantly increase respectively at about 1.6 h, 4 h and 6 h. The oxygen
 14 supply was terminated at approximately 6.5 h, causing a large drop in local temperatures inside the
 15 reactor and a high amount of AE. After 10 h, the temperature of the gasification area stabilized at a
 16 lower level, which was only possible because the reaction gas had been switched from air/oxygen to
 17 air. By this point, the AE count rates had also diminished significantly. Nevertheless, effective coal
 18 combustion and stable gasification were attained during the process.
 19

20

The experimentally obtained results demonstrate that many AE events were generated during coal combustion and that the AE activity was closely related to changes in local temperature inside the coal. The AE events seem to have resulted from crack initiation and extension around the coal combustion area under the influence of thermal stress. The number of AE events generated with increasing temperature within the laboratory UCG models was analyzed using statistical methods, as shown in Fig. 8. To determine the relation between AE activity and local temperature change, the countable number of AE events occurring within temperature intervals incremented by 50 or 100 °C were investigated using the AE results obtained from the UCG experiments conducted in this and in our previous study. Variation of AE events during the successive temperature phases was recorded, with data collected during the coal ignition process excluded because the crack numbers during this phase could have been affected by the ignition method and intensity. In Fig. 8, the dots show averages of AE events, and the vertical bars show standard deviations. An examination of the figure reveals that the relation between AE events and temperature under the experimental operating conditions can be roughly described as a polynomial approximation curve. This result indicates that the fracturing activity is proportional to the temperature increment, a relation that can be regarded as resulting from the coal-fracturing mechanism occurring during combustion. Although the time dependence is not described in this figure, the increase in amount of the microcracks will progressively slower and eventually trend to be stable after a long time of operation and without a fast movement of combustion zone. This is also investigated adequately in our past works [54] by evaluating the AE occurring of coal samples under various heating process. The occurred crack volume and density also affect the further development of microcracks with AE. It was found that the cumulative events show a cavity growth deceleration when a certain amount of cracks are generated inside the coal; this is also the reason why high AE count rates were observed in the initial period, while fewer and relatively weak cracks were detected during the burning stabilization stage.

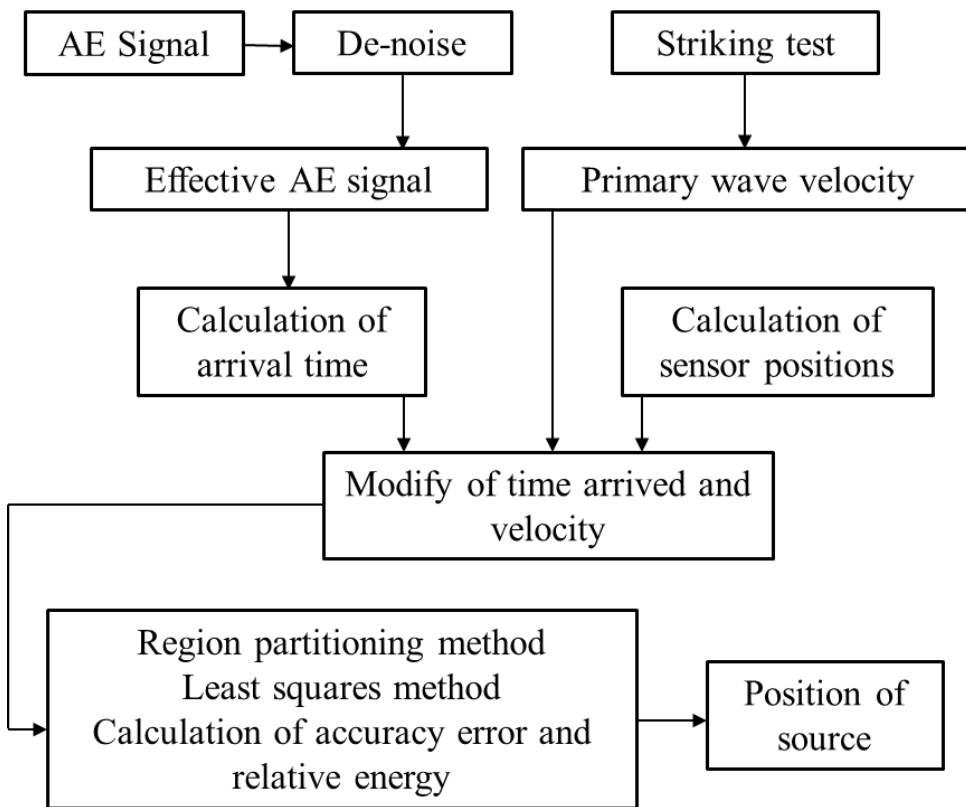

27
28 **Fig. 8.** Variation of AE event generation at different temperature intervals under experimental
29 conditions.

1 3.2. AE source location and crack distribution model

2 As described above, real-time monitoring of AE events and the variation of the AE count rate
3 during the gasification process can identify the extent of fracturing inside the reactor and can even
4 provide an early warning for excessive fracturing in the coal. It was established that the local
5 temperature change strongly affects AE activities caused by fracturing. The cumulative number of AE
6 events changes linearly as the AE count rate increases, and fractures apparently correspond to the
7 number of events that are generated inside the reactor. Furthermore, the cumulative events curve
8 shows a similar form to the coal-temperature curve. To better correlate this AE data with individual
9 cracks within the coal, we further analyzed the results in terms of AE source location and moment
10 tensors.

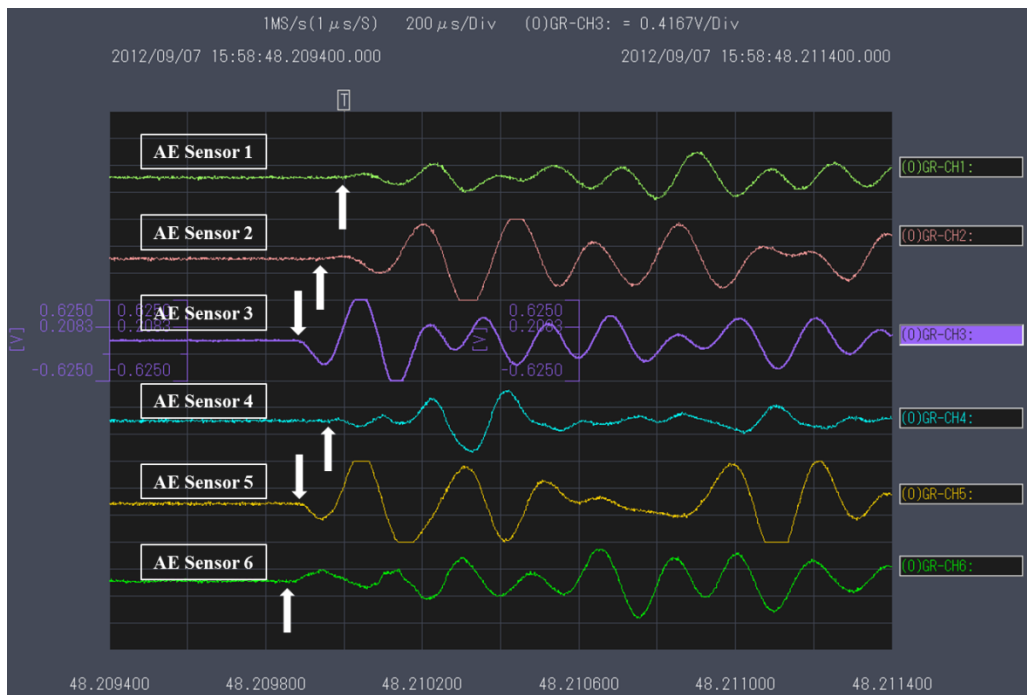

11 3.2.1 AE source location

12 The AE source location can be determined from the differences between the arrival times of waves
13 measured at each AE sensor. Fig. 9 shows a flow chart of the localization algorithm. The program is
14 fed the relative coordinates of sensors in each UCG model. For the initial configuration, it is necessary
15 to calculate the primary wave velocity using a striking test (artificial seismic source) prior to the
16 experiments because the density of the simulated coal seam inside the UCG model is inhomogeneous.
17 As the ray path can be assumed to be linear, a constant primary wave velocity was employed within
18 the localization algorithm.

20 **Fig. 9.** Flow chart for AE source location algorithm.
21
22

1 We can determinate the P-wave arrival time at each sensor from the recorded AE waveforms, as
 2 shown in Fig. 10. The arrows on each sensor's waveform indicate the onset time of the P-wave, i.e.,
 3 the crack initial motion. The relative energy emitted from each crack can be estimated from the square
 4 of the maximum amplitude of the waves. Prior to AE source location, AE signals are filtered in order
 5 to remove noise signals generated by adjustment operations during the experiment. The least-squares
 6 iteration algorithm [55–57] is then used to calculate the position of the AE source according to the
 7 respective sensor coordinates and the primary wave arrival times.
 8

9
 10 **Fig. 10.** Determination of P-wave arrival time (typical signals for an AE source).
 11

12 AE sources located in the above-described UCG model experiments are shown in Fig. 11. The red,
 13 green, and blue spheres in the figure depict the AE sources in the early, middle, and later periods,
 14 respectively. The extent of damage, i.e., the relative energy emitted from cracking, can be
 15 differentiated based on sphere sizes, and the extent and movement of combustion and the gasification
 16 scope inside the coal blocks can be deduced from the AE source locations. In the early stages of the
 17 experiments, the AE sources are mainly concentrated around the ignition points. Subsequently, the AE
 18 source clouds spread and move along the linking holes during the middle periods. Intense AE clouds
 19 are observed in later stages, with fractures spreading and diffusing perpendicular to the direction of the
 20 gasification channel. It is apparent that the gasification zone in the L model test expanded from the gas
 21 inlet to the central region and became enlarged around the gasification channel. At the early stage of
 22 the V model experiment, the AE sources clustered around the left linking hole, suggesting that the
 23 fracturing process inside the gasification area and the AE clustering region was strongly governed by
 24 the inherent inhomogeneity of the coal block. The AE source results from the coaxial models indicate
 25 that the gasification areas evolved from the bottom to the top part along the coaxial hole. In particular,
 26 the C2 model experiment achieved more efficient combustion, with a larger gasification channel and a
 27 longer operational time, than did the C1 model.

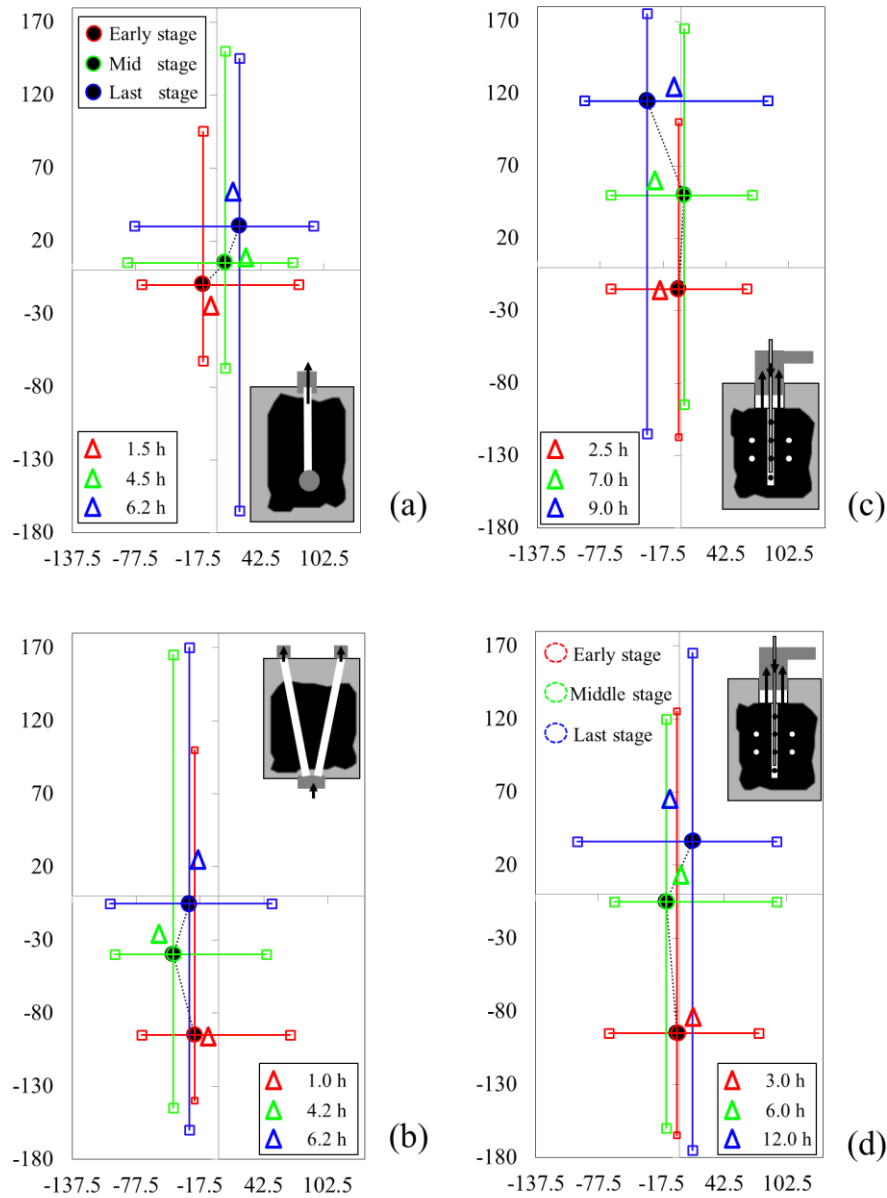

1
2 **Fig. 11.** Results of AE source location in ex-situ reactors for (a) L model, (b) V model, (c) C1
3 model, and (d) C2 model.

4
5 The movements of the centers of gravity within the AE cloud were then investigated (Fig. 12) based
6 on the results of AE source locations. ~~The velocities of cavity growth along the linking hole estimated~~
7 ~~by the AE cloud movement in the respective models are provided in Table 1.~~ The colored circular
8 rings in the figures represent the centers of gravity of the AE cloud calculated using the statistical
9 approach based on the product of the relative AE source energy and the event count. The lengths of the
10 arrows in the horizontal and vertical directions represent the breadth of the AE cloud region.

11 The AE cloud movement was reconfirmed by the center of gravity coordinates of the AE sources; in
12 each time period, the AE cloud movement seems to reflect that of the combustion and gasification
13 region and the cavity growth within the coal. We investigated the distribution of AE sources within
14 three different regions (0–40 mm, 40–80 mm, and 80 mm from the reactor boundary). The flame
15 propagations in these models are also described with the mobility centers of the high temperature zone,
16 as show in this figure. This was roughly estimated using the peak values and combined with the high
17 temperature distribution of local thermocouples at the specific time points. It can be seen that although
18 some level of positions difference exists, the high temperature zone moved broadly consistent with the
19 center of gravity of AE cloud. For a more precise estimation of central position of high temperature
20 zone with temperature data, the higher density arrangement of thermocouples in the model is required.
21 Even so, the movement of AE cloud centers is also proved supporting the observation results

22 The velocities of cavity growth along the linking hole estimated by the AE cloud movement and
23 local temperatures in the respective models are provided in Table 1. The comparison results show that
24 the similar propagation speeds were obtained in these models except the L model. In the L model, the
25 moving range of the AE cloud in horizontal direction (perpendicular to the linking-hole) has no
26 obvious change compared to the propagation along the linking-hole, which caused a relatively lower

1 value of velocity calculation. Despite this, the AE cloud in this model can reflect the region and
 2 movement of the gasification zone accurately yet.
 3

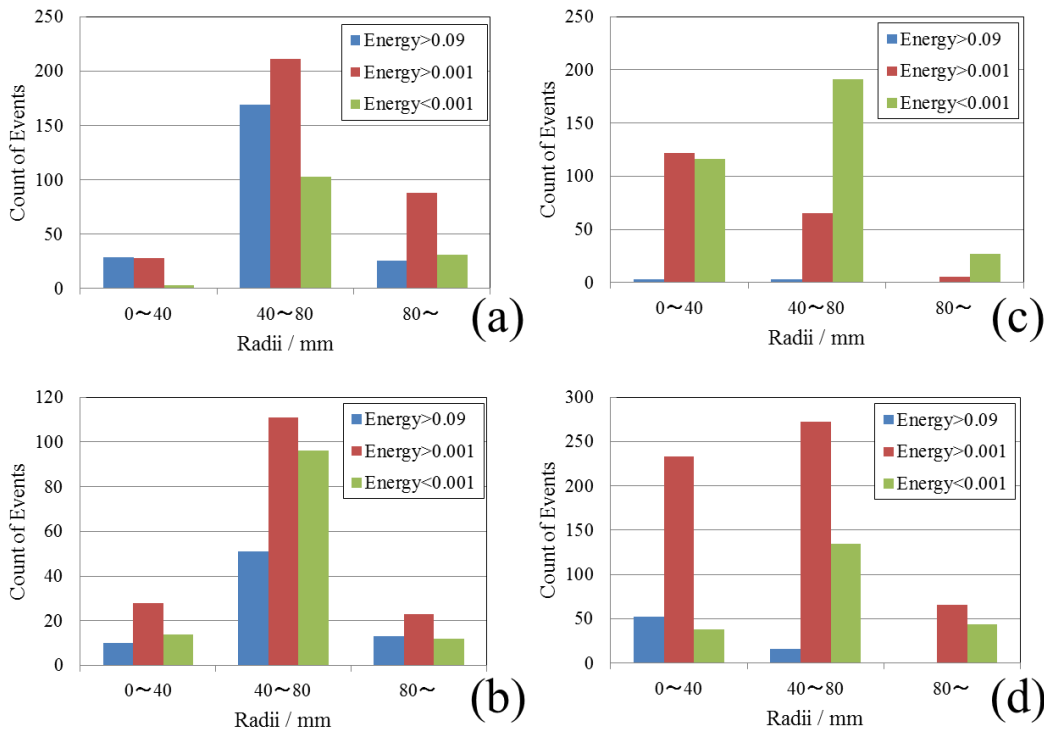

4
 5 **Fig. 12.** Results of AE cloud center evolution in ex-situ reactors for (a) L model, (b) V model, (c)
 6 C1 model, and (d) C2 model. (Colored circular rings denote the centers of gravity of AE cloud;
 7 Colored triangles denote the estimated high temperature zone centers.)
 8

9 **Table. 1.** Estimation of cavity growth velocities in the ex-situ reactors for (a) L model, (b) V model,
 10 (c) C1 model, and (d) C2 model.

Model No.	L-shaped (L)	V-shaped (V)	Coaxial (C1)	Coaxial (C2)
Velocity of Cavity Growth (cm/h) with AE cloud center	0.8	2.1	1.9	3.9
Velocity of Cavity Growth (cm/h) with local temperature	2.0	2.5	1.8	3.1

1 The relative energy of sources obtained from the AE parameters was regarded as a damage index,
 2 as shown in Fig. 13. It is seen that AE sources with high energy clustered around the linking hole (0–
 3 40 mm) in the L and V models. The maximum clustering of relatively intensive AE was concentrated
 4 in the region between 40–80 mm, except for the C1 model (Fig. 13(c)). This was because fracturing
 5 and coal spalling were generated in the vicinity of the cavity roof and developed along with the
 6 damage progress. In the C1 model, a significant number of sources with lower relative energy (<0.001)
 7 clustered in regions close to the coaxial hole. AE activity in terms of energy and quantities was higher
 8 in the C2 model than in the C1 model under the same experimental conditions.
 9

10
 11 **Fig. 13.** Estimation of AE source (relative energy) distributions at different regions around
 12 gasification channel in ex-situ reactors for (a) L model, (b) V model, (c) C1 model, and (d) C2 model.
 13

14 As discussed above, the locations of the AE sources visually correlated with crack initiation and
 15 extension inside the coal. The AE cloud center movement also reflected the combustion area size and
 16 the cavity growth in the gasifier. The AE sources and crack distribution models show that most cracks
 17 were generated at the fracture position and around the combustion area. The region where the AE
 18 sources clustered also corresponded to the local high-temperature zones measured by thermocouples.

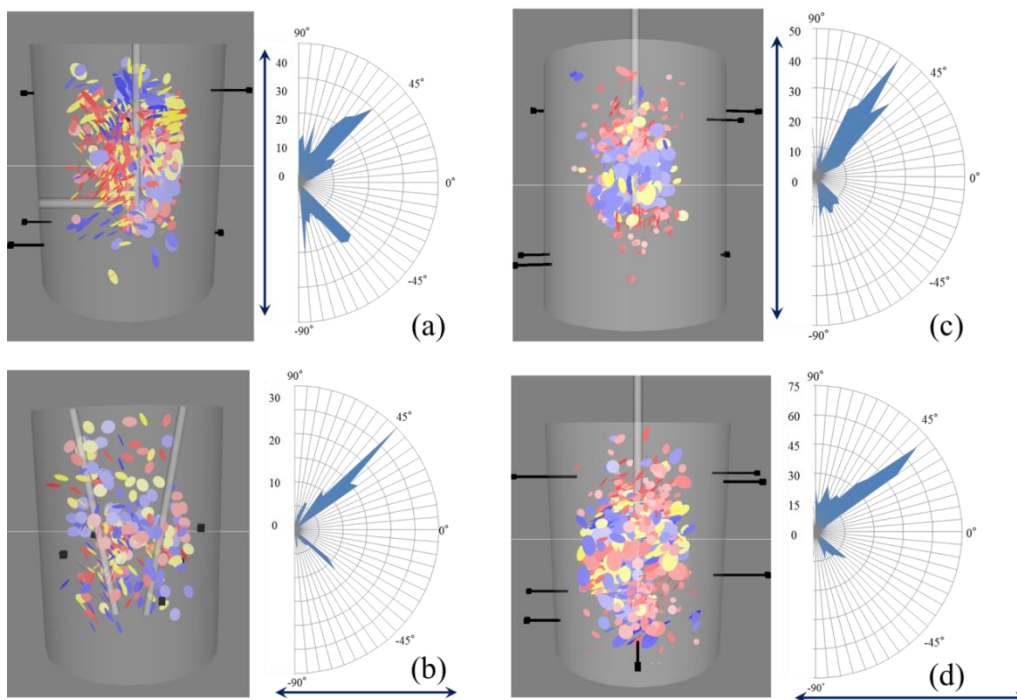

19 **3.2.2. Moment tensor analysis**

20 As discussed above, AE parameter analysis was used to evaluate crack initiation and extension
 21 under UCG operation based on monitored waveforms and parameters such as count rate, event
 22 occurrence, relative energy, etc. We then quantitatively estimated cracking and damage mechanisms in
 23 coal during the gasification process using moment tensor analysis [58, 59] of the AE results of located
 24 AE sources. Arrival times and amplitudes of crack initial motions were determined and 3D source
 25 location models were obtained using differences in arrival times at each sensor. Based on the

1 amplitudes, moment tensor components were then calculated, and the source time function was
 2 calculated using the moment tensor components [60, 61] under the assumption of the Haskell slant
 3 function [62]. Using this information, crack distribution models were constructed from the obtained
 4 source time function based on the Combined Geometric-Mechanical Models (proposed by Ivanova)
 5 [63]. This procedure allowed us to determine the proportion of shear and tensile crack contributions on
 6 the AE sources and to classify cracks by types of dominant motion. By modeling cracks as disks with
 7 zero thickness, moment tensor analysis allowed us to obtain information on source type and
 8 orientation. Such analysis can provide quantitative information on the 3D location of cracks, crack
 9 type, crack orientation, and the direction of crack motion, and makes it possible to visualize the
 10 cracking process inside the UCG gasifier.

11 Crack distribution models estimated using the moment tensor analysis are shown in Fig. 14. The
 12 cracks are represented by multipronged disks in the 3D crack distribution models. Tensile- and shear-
 13 type fractures can also be confirmed. Pink and blue disks represent, respectively, tensile and shear
 14 fractures, with mixed-mode fractures indicated by gradients of purple and yellow. The center of each
 15 crack disk is located at the coordinates of its respective AE source location, and the disk radii show the
 16 relative AE energy. Corresponding to the AE source location results, the L-shaped linking-hole model
 17 cracks were generated in the early stages mainly around the ignition area, after which the cracking area
 18 extended to the central part. In the L and V models, cracks were spread widely all over the reactor as
 19 the damage progressed in the gasification process. In the C1 model, cracks were mainly concentrated
 20 in a limited region around the coaxial hole in the middle-upper part of reactor. In the C2 model, cracks
 21 were located over a wider area and many AEs occurred all over the reactor, from the bottom to the top
 22 part, along the coaxial hole.

23

24

25 **Fig. 14.** Results of moment tensor analysis and directions of tensile crack motions in ex-situ
 26 reactors for (a) L model, (b) V model, (c) C1 model, and (d) C2 model (arrow shows direction of
 27 stratified plane of coal).

The crack distribution models revealed what type of crack was dominant inside the coal block. **Table 2** lists the number of tensile, shear, and mixed-mode cracks identified by moment tensor analyses of the four experiments. To estimate the fracture mechanism from the cumulative damage induced by the gasification process, we also assessed the ratio of each type of crack. In the early and middle stages of the L model, tensile-type cracks are highly represented (55.4%/53.9% > 23.0%/35.5%) around the linking hole. The ratio of shear cracks in the V model slightly increases from the middle (33.7%) to the later stage (39.7%). By contrast, the ratio of tensile cracks decreases from the middle (49.0%) to the later stage (32.5%). It was determined that the cracking behavior produced over the three stages by the C2 model represented by the contribution of tensile and shear mode cracks was more significant than in the C1 model owing to differences in operational conditions (radius of drilling hole, feed gas rate, and operation time) applied in the respective experiments. Our results also show that tensile failure occurred through a major microscopic failure mechanism in the vicinity of the gasification channel.

Table 2. Compositions of each crack type (tensile-, shear-, and mixed-type cracks) in ex-situ reactors.

Model No.	Early stage			Middle stage			Later stage		
	Tensile e-type crack (count)	Shear -type crack (count)	Mixed d-type crack (count)	Tensile e-type crack (count)	Shear -type crack (count)	Mixed d-type crack (count)	Tensile e-type crack (count)	Shear -type crack (count)	Mixed d-type crack (count)
L (L-shaped)	41 (55.4%)	17 (23.0%)	16 (21.6%)	76 (53.9%)	50 (35.5%)	15 (10.6%)	233 (40.7%)	209 (36.6%)	130 (22.7%)
V (V-shaped)	30 (51.7%)	16 (27.6%)	12 (20.7%)	51 (49.0%)	35 (33.7%)	18 (17.3%)	39 (32.5%)	83 (39.7%)	47 (27.8%)
C1 (Coaxial)	97 (52.7%)	56 (30.4%)	31 (16.9%)	126 (70.8%)	35 (19.7%)	17 (9.6%)	92 (50.6%)	65 (35.7%)	25 (13.7%)
C2 (Coaxial)	26 (46.4%)	17 (30.4%)	13 (23.2%)	54 (43.6%)	46 (37.1%)	24 (19.3%)	283 (47.9%)	187 (31.6%)	121 (20.5%)

As shown in **Fig. 14**, the directions of the crack faces were also investigated. The arrows on the right-hand figures show the general direction of the stratified plane of coal. The linking holes in the L and C1 models were drilled parallel and as closely as possible to the stratified plane of the coal block. By contrast, the drilling holes were set as nearly perpendicular to the stratified plane as possible in the V and C2 models. In the L and C1 model experiments, the dominant crack motion directions (tensile cracks only) concentrated primarily at between 50° and 90° to the stratified planes (**Fig. 14(a)** and **14(c)**). Similarly, the major directions of crack motion in the V and C2 models coincided with the major stratified planes (25°–45°) (**Fig. 14(b)** and **14(d)**). As a result, the dominant failure directions in these gasification processes were close to the direction of the major stratified plane of coal. **Fig. 15**

1 shows the distribution of dominant failure in different regions. The figure indicates that shear-type
 2 cracks clustered around the linking hole (0–40 mm) in the central region, while tensile-type cracks
 3 were distributed outward from the combustion region (40–80 mm and 80 mm). The shear- and tensile-
 4 mode cracks comprised 75% - 85% of the total sources. These results indicate that the different
 5 temperature fields of distinct locations within the reactor induced differential fracturing behavior in the
 6 coal. The percentages of tensile/shear cracks are almost identical among the UCG models, which
 7 shows that the ratios of the two crack types did not differ significantly in the coal under the
 8 gasification process.

9

10

11 **Fig. 15.** Estimation of crack (tensile-type crack, shear-type crack and mix-mode crack) distributions
 12 at different regions around gasification channel in ex-situ reactors for (a) L model, (b) V model, (c) C1
 13 model, and (d) C2 model.

14 **3.2.3. Implement of AE in real UCG**

15 For optimizing the UCG operations and reducing the potential risks of environment and
 16 underground water, it is necessary to monitor the gasification process and understand the fracturing
 17 activities occurring in the coal seam, particularly in the zone near the gasification cavity exposed by
 18 the propagation of the combustion fracture. In our study, acoustic emission (AE) technology was
 19 employed as a supplement to traditional measurements, e.g., temperature and gas, in order to monitor
 20 fracturing and cavity evolution during the UCG process.

21 For the in situ UCG, a real-time monitoring and control system is necessary for safe and efficient
 22 gasification. From our study, the AE technology is verified as a reliable approach for monitoring and
 23 evaluating the gasification process in laboratory-scale UCG when combined with the traditional
 24 measurements. For the real UCG, a type of transducer with the low frequency micro-seismicity, i.e., a

1 geophone, which is functionally similar to the AE accelerometer employed in this study, could be used
2 for monitoring the fracturing activity and gasifier's structure in underground. The geophone is a
3 ground motion transducer that can convert the ground damage and movement in the voltage signal.
4 Any deviation in this measured voltage from the base line is regarded as micro-seismic response,
5 which is used for analyzing the structure of underground gasifier in coal seam. As with the AE sensor,
6 parameters such as event, count rate, and relative energy can be obtained from the geophone by
7 processing the recorded voltage signals. Many different types of geophone are now being
8 manufactured nowadays and are used for the measurement of machine vibration, earthquakes, oil
9 exploration, and conventional mining. In our follow-up study of UCG, the new-type three-component
10 geophones will be employed, which is called borehole geophone. This moving coil type geophone is
11 constituted by two components horizontal and one component vertical and potentially provides the
12 higher precision 3-D fracture exploration during real gasification process in underground coal seam.

13 **4. Conclusions**

14 The ex-situ experiments were conducted in order to simulate UCG under several distinct linking-
15 hole UCG models. AE was used to monitor crack initiation and extension and cavity evolution inside
16 the combustion reactor during the gasification process. Our conclusions are as follows:

- 17 1) This study investigated the effects of various linking-hole types and radii, operation times, feed
18 gases, and flow rates on gasification. We confirmed that these operational conditions
19 significantly affect fracture occurrence, crack behavior, cavity growth inside the gasifier, and
20 gasification efficiency.
- 21 2) AE parameter analyses of, e.g., count rate and event occurrence, show that there is a large
22 difference in AE activities under different temperatures during the damage process and between
23 distinct models. The active periods of AE occurrence coincided with local temperature changes
24 over time. These results reveal that AE activity is closely related to the temperature change
25 occurring inside the coal, with AEs apparently resulting from the crack initiation and extension
26 influence of thermal stress.
- 27 3) AE source locations, as determined in this study, could be used to characterize fracture
28 occurrence and crack extension in UCG models in a direct manner. The mobility of the AE
29 cloud center can be derived from the count and relative energy of sources using a statistical
30 approach; by doing this, it is possible to represent high-temperature-zone movement and to
31 estimate the velocity of gasification cavity growth.
- 32 4) The crack distribution model constructed via moment tensor analysis was shown to be effective
33 in understanding the fracturing mechanism of the UCG process. This model can provide
34 quantitative information on the three-dimensional location of cracks, crack types, and
35 orientations of crack initiation in coal during the UCG process.
- 36 5) The moment tensor analysis revealed that tensile failure was a major fracture mechanism of coal
37 that became more dominant as the damage progressed during the gasification process. The
38 distribution of failure modes (tensile/shear cracks) in different regions of the reactor showed that
39 the shear failure was concentrated in the vicinity of the gasification channel.

6) In addition, the general direction of the failure face of the cracks clustered in the reactor could be estimated from crack distribution. We found that the dominant failure directions in these models were close to the direction of the major stratified plane of coal.

The application of the AE technology during UCG is effective for monitoring the gasification process and can play a very important role as a quantitative method for analyzing cracking behaviors and understanding the fracture mechanism in the coal gasifier. AE monitoring makes it possible to visualize cracking processes and cavity evolution inside UCG target coal seams.
